39 **Abstract**

40 Speciation is a fundamental process in evolution and crucial to the formation of  
41 biodiversity. It is a continuous and complex process, which can involve multiple  
42 interacting barriers leading to heterogeneous genomic landscapes with various peaks of  
43 divergence among populations. In this study, we used a population genomics approach to  
44 gain insights on the speciation process and to understand the population structure within  
45 the genus *Sousa* across its distribution in the Indo-Pacific region. We found 5 distinct  
46 clusters, corresponding to *S. plumbea* along the eastern African coast and the Arabian  
47 Sea, the Bangladesh population, *S. chinensis* off Thailand and *S. sahuensis* off Australian  
48 waters. We suggest that the high level of differentiation found, even across geographically  
49 close areas, is likely determined by different oceanographic features such as sea surface  
50 temperature and primary productivity.

53

54 **Introduction**

55 Understanding drivers of population divergence and speciation is a central question in  
56 evolutionary biology. This is especially true in the marine environment where barriers to  
57 dispersal are not as obvious as in the terrestrial environment. A central paradigm in  
58 marine systems is that populations are typically characterized by weak genetic  
59 differentiation due to the potential for long-distance dispersal favouring high levels of  
60 gene flow (Palumbi, 1992). However, several studies have shown that marine megafauna  
61 show high levels of genetic differentiation (e.g. Hess et al, 2013), as is the case for inshore  
62 populations (e.g. Tezanos-Pinto et al, 2009). There are neutral and adaptive processes that

63 can lead to higher than expected differentiation in the marine environment. Neutral  
64 processes include population dynamics caused by birth, death and dispersal of organisms  
65 through different regions and environments, causing genetic drift. Adaptive processes  
66 include local adaptation, where organisms have higher average fitness in their local  
67 environment when compared to individuals elsewhere.

68 Cetaceans are a unique taxonomic group in that species underwent drastic evolutionary  
69 transitions from terrestrial to marine environments (Steeiman et al, 2009). Delphinids, in  
70 particular, have radiated very recently (at around 10-12 Ma, McGowen et al. 2009) and  
71 have populated many different habitats and environments, providing a unique opportunity  
72 to study the role of different evolutionary processes in shaping population structure and  
73 genetic diversity at large spatial, but relatively short temporal scales.

74 Several factors and mechanisms have been suggested as likely to influence and drive  
75 genetic differentiation and speciation in cetacean species. Despite being marine predators  
76 with high mobility and few obvious barriers to dispersal, environmental factors like sea  
77 surface temperature, salinity and ocean currents have been shown to influence patterns of  
78 population structure, as these dictate prey dispersal and availability (e.g. Amaral et al,  
79 2012; Mendez et al, 2011). Other mechanisms such as social interactions, behaviour and  
80 culture, have also been suggested to shape population structure and genetic diversity  
81 (Alexander et al, 2016; Carroll et al, 2015; Kopps et al, 2014; Riesch et al, 2012).

82 Humpback dolphins (*Sousa* spp.) are distributed discontinuously in coastal waters of  
83 West Africa and in the Indian and Western Pacific Oceans and all populations are  
84 currently facing anthropogenic pressures, raising conservation concerns (Braulik et al,  
85 2015; Jefferson and Smith, 2016b; Parra and Cagnazzi, 2016). This genus comprises four  
86 species: *S. teuszii* in the Eastern Atlantic Ocean along the west African coast, *S. plumbea*

87 in the Western Indian Ocean, *S. chinensis* distributed in the Eastern Indian and Western  
88 Pacific Oceans and *S. sahuensis* in Northern Australia and New Guinea (Jefferson and  
89 Rosenbaum, 2014) (Figure 1). However, the exact eastern limit of *S. plumbea* in the Bay  
90 of Bengal and the western limit of *S. chinensis* are poorly known. In terms of external  
91 appearance,; *S. plumbea* has a darker coloration with little spotting and a prominent dorsal  
92 fin hump; *S. teuszii* has a similar appearance to that of *S. plumbea* but with significantly  
93 shorter rostra and lower tooth counts; *S. chinensis* has light adult coloration, often with  
94 bluish gray spotting and lacks the prominent dorsal hump; *S. sahuensis* has no visible  
95 dorsal fin hump and the dorsal fin is low and triangular, with adults having a dark grey to  
96 grey back and a lighter belly (Jefferson and Rosenbaum 2014). Analyses conducted to  
97 date suggest high levels of population genetic structure within both *S. plumbea* and *S.*  
98 *chinensis* and a highly differentiated population in the Bay of Bengal (Amaral et al, 2017;  
99 Mendez et al, 2013). Oceanographic features such as sea surface temperature and primary  
100 productivity have been suggested as important drivers of population differentiation in  
101 these animals (Amaral et al., 2017; Mendez et al., 2011).

102 The Bay of Bengal is a marine region in the Northern Indian Ocean that supports an  
103 impressive variety of cetaceans, but with little knowledge on the evolutionary processes  
104 acting on those species (Mansur et al, 2012; Smith et al, 2008). The extreme infusion and  
105 redistributive dynamism of biological productivity in this region is a rare ecological  
106 condition that supports cetaceans in numbers generally much larger than other  
107 populations in the region (Mansur et al., 2012). While little is known about the  
108 morphological differences in the highly-differentiated humpback dolphin population  
109 occurring in this region, it has been hypothesized that the relatively rare environmental  
110 conditions in the Bay of Bengal explains its genetic distinctiveness (Amaral et al., 2017).

111 Other marine species occurring in this area have also shown high levels of genetic  
112 differentiation (e.g. Li et al, 2015).

113 In this study we aim to build on our previous work that used mtDNA and three nuclear  
114 markers to investigate genetic connectedness of Indo-Pacific humpback dolphin  
115 populations. Using a population genomics approach, we aim to investigate patterns of  
116 genome wide differentiation in Indo-Pacific humpback dolphins across the Indian and  
117 West Pacific Oceans.

118

## 119 **Material and Methods**

120

### 121 **Sample collection and Sequencing**

122 Our total data set consisted of 30 samples obtained from stranded or biopsied humpback  
123 dolphins, which were selected from a set of samples already used in previous studies  
124 (Mendez et al., 2013, Amaral et al., 2017). Representing the entire distribution range of  
125 the *Sousa* genus in the Indo-pacific region, our data set contains samples from Southeast  
126 Africa (SEA - South Africa and Mozambique n=6), Arabian Sea (OM - Oman, n=8), Bay  
127 of Bengal (BAN - Bangladesh, n=10), Indo-China (CHI - Thailand, Hong Kong and  
128 Taiwan, n=4) and Northern Australia (AUS, n=2) (Figure 1).

129 The genomic DNA from tissues samples already preserved in ethanol (96% v/v) or in  
130 sodium chloride-saturated 20% dimethyl sulphoxide (DMSO) solution, was extracted  
131 using QIAamp Tissue Kit (QIAGEN, Valencia, CA, USA) and its concentration  
132 measured using a Qubit Fluorometric Quantitation (ThermoFisher). The samples were then  
133 shipped to the Cornell University Institute of Biotechnology's Genomic Diversity Facility  
134 (<http://www.biotech.cornell.edu/brc/genomic-diversity-facility>) where the GBS

135 (genotyping-by-sequencing) data was generated. Sequencing libraries were constructed  
136 using the restriction enzyme *PstI* (CTGCAG) by a genotype-by-sequencing protocol  
137 (Elshire et al, 2011). Unique oligonucleotide barcodes were added to each sample for  
138 multiplexed sequencing on an Illumina HiSeq 2000 (Illumina, San Diego, CA, USA).  
139 Template-controls were included with the batch of samples. Single-end reads were  
140 generated with an average length of approximately 100 bp.

141

## 142 **Data processing**

143 Demultiplexing, initial quality control, assembly, and SNP discovery were completed in  
144 the TASSEL pipeline v3.0.174 (Glaubitz et al, 2014), which was specifically designed  
145 for GBS datasets. The killer whale genome was used as a reference to identify single  
146 nucleotide polymorphisms (SNPs) (*O. orca*, Oorc\_1.1, 200.0x coverage, (Foote et al,  
147 2015; Morin et al, 2010) using bwa (v0.7.8-r455; Li and Durbin, 2009).

148 The TASSEL pipeline relies on the number of times a given tag has been observed as an  
149 indicator of sequence quality, and not quality scores, as these are frequently not indicative  
150 of sequence quality in short reads as those obtained in a GBS approach (Dohm et al, 2008;  
151 Eren et al, 2013; Glaubitz et al, 2014). The first step of the pipeline consists in processing  
152 and collapsing all barcoded reads into a set of unique sequence tags, with one TagCounts  
153 file produced per input FASTQ file. These separate files are then merged into a single  
154 master file and the tag list is aligned to the reference genome. The barcode information  
155 in the original FASTQ files is used to infer the number of times each tag in the master  
156 file is observed in each sample and these counts are stored in a different TagsByTaxa file.  
157 This information is then used to discover SNPs at each set of tags with the same genomic  
158 position and filter the SNPs based upon the proportion of taxa covered, minor allele

159 frequency (MAF = 0.1), linkage disequilibrium (minimum median population LD( $R^2$ )  
160 was set to 0.1) and inbreeding coefficient ( $F = 1 - H_o/H_e$ , where  $H_o$ - observed  
161 heterozygosity and  $H_e$  – expected heterozygosity) (Glaubitz et al, 2014).

162 After the SNP calling obtained with the TASSEL pipeline, blank-controls and 3  
163 individuals were excluded due to missing data, producing a final data set of 27 individuals  
164 (Table S1). For these individuals, we applied additional filters to further reduce false  
165 positive SNPs for subsequent analysis. Firstly, limits for the genomic depth of coverage  
166 were calculated and applied for each individual in RStudio (v1.0.136; RStudio Team  
167 (2016); R Core Team (2016)) using a custom script (V. Sousa). The calculation  
168 corresponded to 1/3 of the mean-depth for the minimum limit and the double of the mean-  
169 depth for the maximum limit. This calculation was applied because it considers the  
170 average coverage of each individual. Secondly, to minimize the genotyping error that  
171 could come from a heterozygosity excess, we performed the Hardy-Weinberg  
172 Equilibrium test using the hardy option in VCFtools v0.1.15 (Danecek et al, 2011). The  
173 sites with  $P$ -values significant at the 0.01 level were excluded. Non bi-allelic sites as well  
174 as sites with missing data higher than 50% were also removed using VCFtools.

175 A filter for Minimum Allele Frequency (hereafter MAF) was also applied to the raw data  
176 as the initial filter of MAF = 0.1 applied in TASSEL seemed very conservative. We used  
177 two different values of MAF (2 and 5%) to understand how this choice would affect  
178 subsequent analyses, since rare variants could be false positives of the sequencing  
179 protocol but could also be important genetic variation that can have true genetic effects  
180 in the population (Nielsen et al, 2012; Whitlock and Lotterhos, 2015).

181 We used two different datasets in all the population structure analyses described in the  
182 next section. After this step, each data set was converted to various formats using

183 PGDSpider (v2.1.1.3; Lischer and Excoffier, 2012) for subsequent analyses. The  
184 application of the MAF filter greatly reduced the number of SNPs to analyze, but had no  
185 effect on the patterns obtained, therefore we chose to use the dataset with the high  
186 number of SNPs (19 462) to generate the results presented in Figures 2-5.

187 In order to measure the genetic differentiation between populations, we used the  
188 `snpgdsFst` function in the `SNPRelate` package (Zheng *et al*, 2012). The estimator of  
189 (Wright, 1951)  $F_{ST}$  (hereafter  $F_{ST}$ ) was calculated following the approach of (Weir and  
190 Cockerham, 1984). We only compared populations with sample sizes higher than 5,  
191 Bangladesh, Arabian Sea and East coast of Africa, and results are just preliminary.

192

### 193 **Population structure**

194 To infer population structure in the genus *Sousa*, we first used a discriminant analysis of  
195 principal components (DAPC) to identify genetic clusters. DAPC is a multivariate  
196 approach that transforms individual genotypes using principal components analysis  
197 (PCA) prior to a discriminant analysis (DA) (Jombart *et al*, 2010). This maximizes the  
198 differentiation between groups while minimizing variation within groups and was  
199 conducted using the `dapc` function in the *Adegenet* package (v2.1.1; Jombart et al, 2008).  
200 Since DAPC requires group assignment *a priori*, we employed a K-means clustering  
201 algorithm implemented in *Adegenet* to identify the optimal number of clusters from  $K =$   
202 1 to  $K = 10$ . Different clustering solutions were then compared using Bayesian  
203 Information Criterion (BIC), and to avoid over-fitting of discriminant functions, we used  
204 Alpha-score optimization to evaluate the optimal number of principle components (PCs)  
205 to retain in the analysis, as described in Jombart et al, (2010).

206 Second, we estimated individual genetic ancestry using sNMF (Frichot et al, 2014)  
207 through snmf function in the *LEA* package (v1.6.0; Frichot and François 2015), and the  
208 program STRUCTURE (v2.3.2) (Pritchard et al, 2000). Both programs compute  
209 proportion quantities called ancestry coefficients that represent the proportion of an  
210 individual genome that originate from multiple ancestral gene pools (Pritchard et al.,  
211 2000; Frichot et al., 2014). While sNMF generates comparable results to those obtained  
212 from STRUCTURE, it does not require Hardy-Weinberg equilibrium assumptions  
213 (Frichot et al., 2014).

214 The ancestry coefficients were estimated from a specified number of ancestral  
215 populations (K). For sNMF, the ancestry coefficient was calculated for K 1 to 10 using  
216 100 replicates for each K. The preferred number of K was chosen using a cross-entropy  
217 criterion based on the prediction of masked genotypes to evaluate the error of ancestry  
218 estimation. For STRUCTURE, a correlated allele frequency model with no admixture  
219 was used (Hubisz et al, 2009). We conducted 20 runs for each K value (1-6) with a burn-  
220 in of 10,000 repetitions for each value of K followed by 100,000 MCMC repetitions. To  
221 determine the best value of K we employed two approaches. We used an iterative  
222 approach based on the  $\Delta K$  statistic (Evanno et al, 2005) and also used the  $\ln(\Pr(X|K))$   
223 values in order to identify the K for which  $\Pr(K=k)$  is highest, as described in Pritchard  
224 et al. 2000. Both approaches were conducted using CLUMPAK (Kopelman et al, 2015)  
225 and STRUCTURE HARVESTER (v0.6.94; Earl and vonHoldt, 2012).

226 A maximum-likelihood framework was also applied to infer phylogenetic relationships  
227 between populations. The analysis was implemented using RAxML (v8.2.11;  
228 Stamatakis, 2014) in which we carried out 1,000 inferences using the GTR model with  
229 no rate heterogeneity modelled (ASC\_GTRCAT ). The branch support was estimated

230 using bootstrap by a majority-rule criteria as implemented in RAxML and visualized  
231 simultaneously in a single consensus tree (Holland et al, 2005) in Figtree (v1.4.3;  
232 Rambaut 2016). The consensus tree was set at 0.1, which means that bipartitions that  
233 appeared in at least 200 of the 2,000 bootstrap trees participated in network construction.  
234 RAxML was run using the two data sets (Table 1).

235

## 236 **Results**

237 We generated genome-wide SNPs for 30 individuals, 3 of which were excluded due to  
238 high levels of missing data (higher than 90% of missing SNPs - CHI12,14, 13), producing  
239 a final data set of 27 individuals (Table S1) that were used for the downstream analysis:  
240 Southeast Africa (SEA - South Africa and Mozambique n=6), Arabian Sea (OM - Oman,  
241 n=8), Bay of Bengal (BAN - Bangladesh, n=10), Thailand n=1 and Northern Australia  
242 (AUS, n=2) After the TASSEL pipeline, 55615 SNPs were obtained, and this number  
243 was reduced to a range of 11591 – 19 462 SNPs, depending on the value of MAF used.

244

## 245 **Population structure and differentiation**

246 No differences were found in the initial exploratory analyses using the two datasets  
247 obtained using different filters. All the results presented below correspond to the results  
248 obtained with 19 462 SNPs.

249 The clustering analysis performed in STRUCTURE resulted in the best value of K=3 if  
250 we consider the Evanno method and of K=4 if we consider the highest value of  $\ln(\Pr(X|K))$   
251 (Table 2). The results obtained using sNMF showed K=4 as the best fitting number of  
252 clusters (Figure 2). The overall pattern obtained in these two clustering methods  
253 corresponds to the separation of the three species, *S. sahulensis*, *S. plumbea* and *S.*

254 *chinensis* (Figures 2, 3, 4 and 5) and a fourth cluster including the subdivision within *S.*  
255 *plumbea* separating the populations from the African coast and the Arabian Sea. The *S.*  
256 *chinensis* population of Bangladesh is clearly separated from all other populations. In  
257 addition, both STRUCTURE and SNMF analyses showed the individual from Thailand  
258 as an individual with a mixed ancestry from Bangladesh, Oman, East African coast and  
259 Australia (Figure 2). The DAPC results show five clearly separated clusters (Figure 3).  
260 For this analysis, 5 PCs were retained as indicated by the a-score (Figure S1) and the best-  
261 fitting value of K was chosen according to the BIC plot (Figure S2).  
262 The preliminary  $F_{ST}$  analysis show results consistent with those described above, with  
263 high levels of genetic differentiation found between the Bangladesh population and the  
264 Arabian Sea and the African coast populations. The lowest value of differentiation is seen  
265 between the Arabian Sea and the African coast populations (Table 1).

266

### 267 **Phylogenetic relationships**

268 Using the ML method, the phylogenetic tree showed the same pattern mentioned above.  
269 Three main and highly supported clusters, corresponding to the three described species  
270 are seen. The subdivision within *S. plumbea* is also identified and supported with  
271 bootstrap values of 100 (Figure 5). The individuals from Bangladesh and the individual  
272 from Thailand are also found in separate highly supported clusters.

273

### 274 **Discussion**

275 In this study, we conducted for the first time a genome-wide population analysis of  
276 humpback dolphins occurring in the Indo-Pacific Ocean. We found high levels of species  
277 and within-species divergence consistent with previous studies using mitochondrial DNA

278 and five nuclear loci, that support the currently recognized species of *Sousa* as well as  
279 strong genetic subdivisions within species.

280

### 281 **Population structure and environmental drivers**

282 Our study supports previous findings that humpback dolphins in the Indo-Pacific region  
283 appear to be divided in five main genetic clusters. The three species already described (*S.*  
284 *plumbea*, *S. chinensis* and *S. sahulensis*) and the Bangladesh population are strongly  
285 differentiated. Within *S. plumbea*, we further obtained a genetic division, albeit weaker,  
286 between the African coast and the Arabian Sea. The Bangladesh population in the Bay of  
287 Bengal seems to be genetically more similar to *S. sahulensis* and *S. chinensis*, even though  
288 the dolphin's outer body morphology is similar to the other species, *S. plumbea*. Since  
289 this population is located in a transition region between *S. plumbea* and *S. chinensis* and  
290 shows morphological characters of both species, hybridization between the two types was  
291 hypothesized (Jefferson and Rosenbaum, 2014; Mendez et al., 2013). However, both  
292 previously obtained mitochondrial DNA data and the genomic DNA obtained in this  
293 study show congruent results, ruling out the hybridization scenario (Amaral et al., 2017).  
294 Based on our previous results with the mitochondrial DNA and those obtained in this  
295 study, we suggest that this population may constitute a separate taxonomic entity, but  
296 additional evidence with samples from surrounding areas is needed. This region seems to  
297 harbour a strong potential for endemism and speciation, as seen in the high levels of  
298 genetic differentiation obtained for a sympatric dolphin species, the Indo-Pacific  
299 bottlenose dolphin (Amaral et al., 2017), as was well as other mobile marine species (e.g.  
300 Li et al., 2015). The northern Bay of Bengal is located in an ecological “cul-de-sac” and  
301 has extraordinary oceanographic conditions, including intrusion of massive and dynamic

302 freshwater and sediment flow from among the world's largest river systems, leaf litter  
303 and other bio-productivity from a large mangrove forest. In addition, this region has an  
304 upwelling from a deep submarine canyon which supports a large sediment fan and a  
305 seasonally reversing current gyre with associated meso-eddies that retain and redistribute  
306 nutrients (Cheng et al, 2013; Hussain and Acharya, 1994). Together these local conditions  
307 are unique in terms of their dynamics and scale, and likely explain the genetic  
308 distinctiveness found in marine organisms occurring in the northern Bay of Bengal.

309 The sample from Thailand showed a mixed ancestry with genetic contributions from *S.*  
310 *sahulensis* and the Bangladesh population, and on a much lower level with *S. plumbea*.  
311 This suggests that it could be a hybrid individual and more samples are needed to  
312 understand the level of genetic distinctiveness of individuals occurring in this region.

313 The genetic division obtained with *S. plumbea*, separating the southeast South Africa  
314 population from the Arabian Sea population, has already been described using mtDNA  
315 and a few nuclear markers (Mendez et al., 2013; Amaral et al., 2017). Both these regions  
316 are characterized by unique oceanographic features that could explain this pattern. The  
317 coast of Oman is part of the Arabian Sea Upwelling Province, where the annual monsoon  
318 influences the system of currents and the occurrence of rich upwelling areas (Longhurst,  
319 2006). The coasts of Mozambique and South Africa are part of the Eastern African  
320 Coastal Province, which includes the Mozambique Channel, and is also influenced by a  
321 series of gyres and currents, creating unique environmental conditions. Surface currents  
322 and other oceanographic variables such as water turbidity and chlorophyll concentration  
323 are known to influence and drive distribution patterns in mobile marine species, such as  
324 turtles (e.g. Bass et al, 2006), common dolphins (Amaral et al., 2012) and franciscana

325 dolphins (Mendez et al, 2010) and could therefore also determine the patterns of genetic  
326 differentiation seen in humpback dolphins.

327 The overall phylogeographic pattern obtained in this study, with distinct lineages in the  
328 east and west of the Indo-Pacific Ocean has also been described in other marine species  
329 (Ahti et al, 2016; Bowen et al, 2016; Farhadi et al, 2017; Li et al, 2015). This pattern may  
330 have resulted from restricted connectivity of populations across the Sunda shelf  
331 (southeast extension of the continental shelf of Southeast Asia comprising the Malay  
332 Peninsula, Sumatra, Borneo, Java and Bali) during periods of low sea level in the glacial  
333 periods of the Pleistocene (Vorisi, 2000).

334

### 335 **Final considerations**

336 In the present study we analysed 19 462s genome-wide SNPs, following a population  
337 genomics approach to evaluate the variability and differentiation in Indo-Pacific  
338 populations of the genus *Sousa*. Our work supports previous studies where five clusters  
339 were observed. The three Indo-Pacific species, *S. sahalensis*, *S. plumbea* and *S. chinensis*  
340 were clearly separated from each other with absence of gene flow between them. Genetic  
341 segregation within *S. plumbea* was also observed separating the African Coast population  
342 from the Arabian Sea and the Bangladesh population was highly differentiated from the  
343 other species with little gene flow between them pointing towards the possibility of a fifth  
344 species of humpback dolphin. Oceanographic features have been suggested as important  
345 factors driving the divergence of these populations. The discontinuous range resulting  
346 from past sea level rise has also likely contributed to population isolation. Future studies  
347 need to investigate molecular dating to estimate the time of dispersal events and a  
348 biogeographical analysis to study the origin and dispersal of the various populations of

349 *Sousa*. This was the first study to our knowledge, to use genome-wide markers to analyse  
350 the population divergence in these dolphin species.

351 The clarification of the population structure within *Sousa* and the processes involved in  
352 this differentiation is extremely important for the conservation of these species. Living in  
353 nearshore habitats with freshwater input and in developing nations heavily influenced by  
354 human activities, makes the genus extremely vulnerable to fatal entanglements in fishing  
355 gear, impacts of vessel traffic and the increasing degradation of their habitat.

356

### 357 **Acknowledgements**

358 This research would not have been possible without the dedicated effort of WCS field  
359 assistants and our research boat crew especially Musa Kalimullah. Samples for this study  
360 were collected under permit from the Ministry of Environment and Forest, Bangladesh.

361 We are grateful to Mr. Yunus Ali, Chief Conservator of Forest, Bangladesh, for his help  
362 with obtaining the CITES export permit for the skin samples used in this study. Funding  
363 for this work was provided by the IWC Small Cetacean Conservation Fund Awarded and  
364 Ocean Park Conservation Foundation Hong Kong to BDS and HCR. We are also grateful  
365 to Dr. Vic Peddemors and the KwaZulu-Natal Sharks Board for contributing with the  
366 samples from South Africa used in this study. The samples from Mozambique were  
367 collected with a financial support from German Dolphin Conservation Society awarded  
368 to LK. We thank the Ministry of Environment and Climate Affairs in Oman for  
369 permission to survey and sample cetaceans in the Arabian Sea. A.R. Amaral was  
370 supported by a grant (SFRH/BPD/79002/2011) from the Portuguese Science Foundation.

371

372

373 **Author contribution**

374 A.R.A. and H.C.R. conceived the study. A.R.A. and C. C. analysed the data and wrote  
375 the manuscript. B.D.S., R.M., T.C., R. B., G.M., G.J.P., M.K., T.A.J., L.K., A.G. and  
376 R.LB Jr., were involved in sample collection.

601 **List of Figures**

602 Figure 1 - Representation of the samples used covering the entire range of the genus *Sousa*  
603 in the Indo-Pacific region. Different symbols correspond to different populations within  
604 each species: ▲ – Southeast Africa; ♦ - Oman; ★ – Bangladesh; ■ – Thailand; ♣ –  
605 China; ♠ - Australia and numbers on the right indicate the final number of samples used  
606 in the analyses.

607 Figure 2 - Results obtained from the population structure analyses of the genus *Sousa* for  
608 A) STRUCTURE and B) SNMF showing the clustering of different populations in  
609 different colors. Bangladesh – Pink; African Coast – Blue; Arabian Sea – Red; Australia  
610 – Yellow. The individual from Thailand is represented by \*. In A) the cluster in green  
611 represents the African coast and Arabian Sea.

612 Figure 3 – Principal Component Analysis (PCA) of the sampled populations of *Sousa*  
613 spp. The first two principal components explaining 55% of the variance are shown.  
614 Identified clusters are color-coded: Bangladesh – pink, African coast and Arabian Sea –  
615 green, Australia yellow, the individual from Thailand in a white box.

616 Figure 4- DAPC results showing five optimal clusters with 5 PCs and 4 DA eigenvalues  
617 used. Bangladesh – Pink; African Coast – Blue; Arabian Sea – Red; Australia – Yellow,  
618 the individual from Thailand is in black.

619 Figure 5 - Maximum Likelihood consensus tree obtained from RAxML with bootstrap  
620 values above 85 shown on branches. The different clusters are represented with different  
621 colours: *S. chinensis* is separated in two clusters, the population from Bangladesh as Pink  
622 and the individual from Thailand is marked with \*; *S. plumbea* separated in two clusters,  
623 the African Coast as Blue, and the Arabian Sea as Red; and *S. sahulensis* from Australia  
624 as yellow.
